Abstract

The three-dimensional temporal instability of rotating boundary layer flows is investigated by computing classical normal modes as well as by evaluating the transient growth of optimal disturbances. The flows examined are the rotating Blasius (RB) and the rotating asymptotic suction layers (RAS), with the rotation axis normal to the basic flow plane. In agreement with an inviscid criterion, streamwise unstable modes are found in both flow cases for anti-cyclonic rotation: at high Reynolds numbers, one obtains the Rossby number unstable range $0 < 1/\text{Ro} < 0.57$ for RB, or $0 < 1/\text{Ro} < 1$ for RAS. Critical Reynolds and Rossby numbers are also determined in both instances. Moreover the dependence of transient growth with respect to wavenumbers, Rossby and Reynolds numbers is presented for both cyclonic and anti-cyclonic régimes. In particular, the *peak* transient growth is computed for a wide range of parameter values within the cyclonic regime and is shown to be reduced by rotation. A scaling analysis with respect to the Reynolds number is performed showing that the standard Re^2 scaling is recovered only at very weak rotation. Optimal disturbances resemble oblique vortices. At weak rotation, they are almost streamwise vortices though their structure departs from the classical non-rotating case. Strong rotation imposes two-dimensionality and the optimal disturbances vary weakly in the spanwise direction and exhibit growth by the Orr mechanism.

Keywords: Instabilities: Boundary Layer, Boundary Layers: 3D, Geophysical Flows: Rotating Flows

I. INTRODUCTION

The standard development of boundary layers may be transformed by various effects, the modification of boundary conditions (riblets, compliant walls) or the presence of bulk forces such as centrifugal¹ and/or Coriolis forces,² to name just a few. In astrophysical, geophysical and technological flows, rotation through the Coriolis effect plays a major role: technological examples appear most notably for turbomachinery but also include rotary atomization nozzles.³ Astrophysical examples include the solar tachocline⁴ and, on a larger scale, accretion disk flow at the disk-star boundary layer.⁵

For shear flows $(U(x, y), V(x, y), 0)$, it is known that rotation along the z -axis can produce an instability generating streamwise oriented vortices, also known as longitudinal rolls.⁶ This instability arises due to the imbalance of pressure and Coriolis forces.¹ Rotating channel flows have been shown to exhibit this instability, in both theory and experiment,^{7,8,9} while rotating free shear flows have been predicted to be likewise unstable.¹⁰

However, this modal instability is present only for a certain range of rotations rates and depends on the direction of the frame rotation vector (here the z -axis) with respect to the vorticity vector of the base flow. When the latter quantities are parallel (anti-parallel), the rotation is called cyclonic (anti-cyclonic). Cyclonic rotation and strong anti-cyclonic rotation are found to stabilize normal modes. On the contrary, weak anti-cyclonic rotation results in unstable streamwise vortices. All these properties have been verified for rotating Poiseuille flow,^{7,8,9} rotating planar wakes and rotating mixing layers.¹⁰ In addition, instability thresholds have been determined in terms of Rossby and Reynolds numbers (the Reynolds number Re and Rossby number Ro are defined explicitly in §III(A)). Such an instability mechanism is fundamentally inviscid and is reduced by the presence of viscosity. For instance, in rotating

Poiseuille flow,⁸ a critical point was found at $Re_C \approx 89$ and Rossby number $Ro = 1$. Even though the boundary layer over a flat plate continues to be an essential prototypical flow in the study of transition to turbulence, rotating boundary layers have been less extensively studied. In one early study,¹¹ it was found that rotating Blasius flow (denoted hereafter by RB) is destabilized by weak anti-cyclonic rotation. However stabilization for stronger anti-cyclonic rotation was not found since strong rotation rates were not considered. This study was limited to a few fixed values of streamwise wavenumbers and no critical point was sought. The first purpose of the present work is to investigate the characteristics of the unstable normal modes of rotational boundary layer flows by emphasizing the ranges of Reynolds and Rossby numbers where the rotational instability is active.

In non-rotating shear flows (plane Couette, Poiseuille, boundary layer flows), nearly streamwise vortices have also been observed during the transition to turbulence (note that no fundamental connection exists between these two kind of streamwise vortices). These are thought to be the result of a *transient growth* process that can occur even when linear stability theory predicts that all modes are stable. The ability of disturbances in shear flows to grow transiently was first proposed by Kelvin¹² and explored by Orr;¹³ later, Ellingson and Palm,¹⁴ Landahl¹⁵ and Hultgren and Gustavsson¹⁶ proposed mechanisms for this growth. Transient growth theory has taken shape more recently see e.g. papers 17,18,19,20, reviews, Refs. 21,22 and the monograph 23. For steady flows, transient growth can be related to the non-orthogonality, with respect to a suitable energy norm, of the eigenvectors of the linear evolution operator. This feature permits certain initial conditions to experience relatively large amplification $G(t)$ at intermediate times even for asymptotically stable flows. The most amplified transient disturbances for boundary layers¹⁸ typically take the form of streamwise vortices. The well known streaks seen in such flows at high levels of free stream turbulence,

are now thought to be formed as these optimal vortices lift up¹⁵ low velocity fluid from the wall region and push down high velocity fluid toward the wall.²⁴ In rotating boundary layers, there exists also a wide range of rotation rates for which the instability is not present and little attention has been paid to this rotationally stable regime. In particular, the possibility that disturbances experience significant *transient growth* in rotating boundary layers, has not been addressed yet (although some preliminary results for rotating channel flow appears in Ref. 23). The second and major purpose of this paper is to study transient growth in rotating boundary layer flows, primarily in the regime where no unstable normal modes are present. Transient growth factors, maximized in time, are calculated for a broad range of wavenumbers and Rossby numbers. Peak transient growth factors, maximized both in time and in wavenumber space, are also computed as a function of rotation. Calculations based on RB flow are presented alongside equivalent calculations based on the rotating asymptotic suction (denoted hereafter by RAS) profile. The base flows are discussed in §II, then in §III the disturbance equations and calculation methods are presented. Results for modal instability and transient growth for both base flows are contained in §IV and the study is concluded in §V.

II. BASE FLOWS

To examine the effect of rotation on boundary layers, we choose as base flows two well-known boundary layer solutions which are rapidly recalled in the following sub-section: the Blasius boundary layer and the asymptotic suction profile.

A. Base Flows without rotation

The paradigmatic Blasius velocity profile $U(y)^{25}$ is related to the streamfunction f by $U(y) = U^* f'(\eta)$ where U^* denotes the free-stream velocity, primes the differentiation with respect to the similarity variable η . More precisely f and η satisfy

$$f''' + \frac{1}{2} f f'' = 0 \text{ with } \eta = y/\Delta(x) \text{ and } \Delta(x) = \sqrt{\nu x/U^*}. \quad (1)$$

The quantity $\Delta(x)$ denotes a boundary layer thickness defined in terms of the free-stream velocity U^* , the downstream distance x and the kinematic viscosity ν . Equation (1) is easily evaluated using straightforward numerical schemes (Falkner-Skan routines built into MATLAB²⁶ were used in this work). Blasius flow includes as well a weak transverse velocity,

$$V(y) = \frac{1}{2} \sqrt{\frac{\nu U^*}{x}} (\eta f' - f), \quad (2)$$

which is zero at the wall and approaches the constant displacement velocity, $V^* = 0.8604 U^* \sqrt{\nu/x U^*}$ as $y, \eta \rightarrow \infty$. The displacement thickness

$$\delta_B = \int_0^\infty \left(1 - \frac{U}{U^*}\right) dy = \Delta(x) \lim_{\eta \rightarrow \infty} [\eta - f(\eta)] = 1.7208 \Delta(x), \quad (3)$$

defines the length scale used to build a Reynolds number $\text{Re} = U^* \delta_B / \nu$.

The non-rotating asymptotic suction profile (denoted hereafter by AS) describes the velocity field obtained when a fluid flows parallel to a surface on which uniform suction V^* is applied. This boundary layer profile

$$U(y) = U^* (1 - e^{-y/\delta_S}); \quad V(y) = -V^* \text{ with } \delta_S = \frac{\nu}{V^*} \quad (4)$$

is a true Navier-Stokes solution and, contrary to Blasius flow, does not vary in the downstream direction. The linear^{25,27} and nonlinear²⁸ stability properties of flow (4) have been

long known: AS flow remains stable for much higher Reynolds numbers than Blasius flow for a Reynolds number based on the displacement thickness (for AS equal to δ_S) and free stream velocity, i.e. $\text{Re} = U^* \delta_S / \nu$. Note that the non-dimensional transverse velocity is such that $V^* / U^* = 1 / \text{Re}$.

B. Base Flows with rotation

Let us now consider a frame rotating along the z -direction with a constant angular velocity Ω (see Fig.1). By applying the usual boundary layer scalings²⁵ to the rotating Navier-Stokes equations, the nondimensional equations read in the limit of large Re ,

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (5)$$

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -\frac{\partial p}{\partial x} + \frac{\partial^2 u}{\partial y^2} + \frac{1}{\text{ReRo}} v \quad (6)$$

$$0 = -\frac{\partial p}{\partial y} - \frac{1}{\text{Ro}} u \quad (7)$$

where the Rossby number is defined such as $\text{Ro} = U^* / 2\Omega\delta$ where δ stands for the displacement thickness ($\delta = \delta_B$ or δ_S). Unless rotation is very strong (i.e. the rotation number $\text{Rot} = (2\text{Ro})^{-1} \gg 1$), the term $\frac{1}{\text{ReRo}} v$ is weak relative to the leading order terms (the strongest rotation numbers used in this study are $\mathcal{O}(1)$) and can thus be neglected in the streamwise momentum equation, (6). A non-rotating boundary layer profile such as the Blasius profile or AS profile, is then preserved in the presence of rotation¹¹ although rotation calls for an added cross-stream base pressure gradient, $dP/dy = -\frac{1}{\text{Ro}} U(y)$ to balance the Coriolis force resulting from the streamwise velocity $U(y)$. The rotating asymptotic suction (RAS) profile continues to be an exact solution of the rotating Navier-Stokes equations if,

in addition to the normal base pressure gradient, $dP/dy = -\frac{1}{\text{Ro}}U(y)$, a streamwise pressure gradient $dP/dx = \frac{1}{\text{ReRo}}V$ is included in the base flow to balance the Coriolis term in the streamwise momentum equation.

In the following stability and transient growth calculations, the downstream variation of boundary layers is not accounted for. Two major hypothesis follow: (a) the streamwise profile is considered at a given streamwise position $x = x_0$, and (b) the transverse velocity component is discarded, i.e. we set $V = 0$. For all RB computations and most RAS calculations (unless otherwise stated), the approximated profile $(U(y), 0, 0)$ will be hence used. However, as mentioned above, RAS flow with $V \neq 0$ is an exact parallel solution of the Navier-Stokes equations; it can thus be used as a test for the validity of the second hypothesis. In the Appendix, a comparison between the two possibilities $V \neq 0$ and $V = 0$ is presented for RAS, based on growth rates and neutral curves of normal modes as well as transient growth. This study shows that the effect of the transverse velocity on the normal modes and transient properties is negligible.

III. MATHEMATICAL FORMULATION

A. Linearized disturbance equations

In a frame rotating along the z -direction with a constant angular velocity Ω (see Fig.1), the dimensionless Navier-Stokes Equations read

$$\frac{\partial \mathbf{u}_{tot}}{\partial t} + \mathbf{u}_{tot} \cdot \nabla \mathbf{u}_{tot} + \frac{1}{\text{Ro}} \hat{z} \times \mathbf{u}_{tot} = -\nabla p_{tot} + \frac{1}{\text{Re}} \nabla^2 \mathbf{u}_{tot}; \quad \nabla \cdot \mathbf{u}_{tot} = 0 \quad (8)$$

where non-dimensionalization has been performed using free stream velocity U^* , displacement thickness δ ($= \delta_B$ or δ_S), and pressure scale $\rho(U^*)^2$. Two dimensionless number then arise: the Reynolds number $\text{Re} = U^*\delta/\nu$, and the Rossby number $\text{Ro} = U^*/2\Omega\delta$.

Following standard methods, the base state velocity²⁹ $(U(y), V, 0)$ and pressure $P(y)$ are perturbed by adding an infinitesimal disturbance (u_p, v_p, w_p) and p_p . These linear perturbations can be assumed to satisfy a modal behavior in x, z , viz.

$$(u_p, v_p, w_p; p_p) = (u(y, t), v(y, t), w(y, t); p(y, t))e^{i(\alpha x + \beta z)}, \quad (9)$$

where α, β are assumed to be purely real. By using normal velocity $v(y, t)$ and normal vorticity

$$\zeta(y, t) = i\beta u - i\alpha w, \quad (10)$$

the linear dynamics is described by one equation governing normal velocity v :

$$\left(\frac{\partial}{\partial t} + i\alpha U + VD\right)(D^2 - k^2)v - i\alpha(D^2 U)v + \frac{1}{\text{Ro}}i\beta\zeta - \frac{1}{\text{Re}}(D^2 - k^2)^2v = 0, \quad (11)$$

and a second equation governing normal vorticity ζ :

$$\left(\frac{\partial}{\partial t} + i\alpha U + VD\right)\zeta - \frac{1}{\text{Ro}}i\beta v + i\beta(DU)v - \frac{1}{\text{Re}}(D^2 - k^2)\zeta = 0, \quad (12)$$

where $k^2 \equiv \alpha^2 + \beta^2$, $D \equiv d/dy$. Equation (11) (resp. (12)) is nothing but the Orr-Sommerfeld (resp. Squire) equation modified to account for rotation. Boundary conditions

$$v = Dv = \zeta = 0 \quad (13)$$

should be imposed at the wall ($y = 0$) and in the far field ($y \rightarrow \infty$). A dynamical system is thus defined for $\mathbf{q}(\mathbf{y}, \mathbf{t}) = (v(y, t), \zeta(y, t))^T$.

B. Normal mode approach

In this work, we study the above problem using two different approaches: the normal mode approach (cf asymptotic dynamics) and the non-normal approach (cf transient dynamics). The first approach consists in recasting the problem in §III(A) into an eigenvalue

problem by assuming $\mathbf{q} = \tilde{\mathbf{q}}(\mathbf{y})e^{-i\omega t}$ where $\tilde{\mathbf{q}} = (\tilde{v}, \tilde{\zeta})^T$ and $\omega = \omega_r + i\omega_i$ are complex. Clearly a mode having $\omega_i > 0$ is unstable. Equations (11)-(12) can then be written

$$i\omega \mathbf{M} \tilde{\mathbf{q}} = \mathbf{L} \tilde{\mathbf{q}} \quad (14)$$

where

$$\mathbf{M} = \begin{pmatrix} D^2 - k^2 & 0 \\ 0 & 1 \end{pmatrix}, \quad \mathbf{L} = \begin{pmatrix} \mathcal{L}_{OS} & \mathcal{R}_{OS} \\ \mathcal{R}_{SQ} & \mathcal{L}_{SQ} \end{pmatrix} \quad (15)$$

with

$$\mathcal{L}_{OS} = (i\alpha U + VD)(D^2 - k^2) - i\alpha(D^2 U) - \frac{1}{\text{Re}}(D^2 - k^2)^2, \quad (16)$$

$$\mathcal{L}_{SQ} = i\alpha U + VD - \frac{1}{\text{Re}}(D^2 - k^2), \quad (17)$$

$$\mathcal{R}_{OS} = \frac{1}{\text{Ro}}i\beta, \quad \mathcal{R}_{SQ} = i\beta(DU) - \frac{1}{\text{Ro}}i\beta \quad (18)$$

It should be emphasized that as a result of rotation, the Orr-Sommerfeld equation is explicitly coupled to the Squire equation since both $\mathcal{R}_{OS}$ and $\mathcal{R}_{SQ}$ are nonzero while only the Squire equation is coupled through $\mathcal{R}_{SQ}$ in the absence of rotation. These equations together with the boundary conditions

$$\tilde{v} = D\tilde{v} = \tilde{\zeta} = 0 \quad (19)$$

imposed at the wall ($y = 0$) and in the far field ($y \rightarrow \infty$) define the eigenvalue problem to be solved. A Chebyshev collocation algorithm developed in previous work³⁰ is implemented. First the semi-infinite domain is approximated by a sufficiently large interval $[0, L]$, a method known to be effective¹⁸. In practice, the domain extended to sixteen displacement thicknesses δ , $L = 16 \delta$. This spatial interval is then mapped to the interval $[-1, 1]$. Finally

eigenfunctions are expanded into Chebyshev polynomials. The number N of polynomials was generally $N = 75$, although as many as $N = 125$ were used to give improved accuracy in some calculations. Collocation points are the standard Gauss-Lobatto points. The eigenvalue problem (14) and boundary conditions (19) are then transformed into a corresponding $2N \times 2N$ matrix problem. To facilitate calculation, the eigenvalue problem (14) is actually written as

$$i\omega\tilde{\mathbf{q}} = \mathcal{L}\tilde{\mathbf{q}} \quad \text{with} \quad \mathcal{L} \equiv \mathbf{M}^{-1}\mathbf{L} . \quad (20)$$

C. Transient Growth Calculations

Transient amplification calculations have also been implemented on the problem in §III(A) according to the singular value decomposition (SVD) method given by Reddy and Henningson²⁰ and the algorithms published in Ref. 23. The main steps of the method are briefly described below; more details can be found in the references. First, the standard kinetic energy norm

$$\|\mathbf{q}(\mathbf{t})\|_E^2 = \int_0^L (|Dv|^2 + k^2|v|^2 + |\zeta|^2) dy \quad (21)$$

is used to measure the magnitude of a disturbance $\mathbf{q}(\mathbf{t})$ at time t . At time t , one can define

$$G(t) = \sup_{\mathbf{q}(0) \neq 0} \frac{\|\mathbf{q}(\mathbf{t})\|_E^2}{\|\mathbf{q}(0)\|_E^2} = \|e^{i\mathcal{L}t}\|_E^2 , \quad (22)$$

where $\mathbf{q}(0)$ is an initial disturbance and $\mathcal{L}$ is the linear operator defined in (20). This quantity $G(t)$ represents the maximum possible energy amplification at time t , optimized over all possible initial disturbances. Finally the maximum or optimal growth is defined as $G_{MAX} = \sup_{t \geq 0} G(t)$. The peak value $G_P(\text{Ro}, \text{Re}) \equiv \sup_{\alpha, \beta} G_{MAX}(\alpha, \beta, \text{Ro}, \text{Re})$ can also be computed. Note that G_{MAX} is associated with a particular initial disturbance which reaches G_{MAX} at a specific time $t_{MAX}(\alpha, \beta, \text{Ro}, \text{Re})$ such that $G_{MAX} = G(t_{MAX})$. Similarly one may

define a specific time $t_p(\text{Ro}, \text{Re})$ related to G_P .

The quantity $G(t)$ is obtained as follows. Assume that the eigenvalues of (20)-(19) are sorted in order of decreasing imaginary part ω_i . One can approximate $G(t)$ by computing the maximum possible energy amplification at time t , optimized over all possible initial combinations of the K eigenfunctions associated with the first K eigenvalues of (20). In this case, it is possible to transform the energy norm of the matrix exponential (22) to an ordinary 2-norm via the following equation

$$\|e^{i\mathcal{L}t}\|_E^2 \approx \|\mathbf{F}e^{-i\Lambda t}\mathbf{F}^{-1}\|^2, \quad (23)$$

where Λ is a $K \times K$ diagonal matrix with the first K eigenvalues $\omega_1, \omega_2, \dots, \omega_K$ along the diagonal and $\mathbf{F}$ is obtained by Cholesky factorization of $K \times K$ Hermitian matrix $\mathcal{M} = \mathbf{F}^H \mathbf{F}$ which is calculated using the inner product of the K eigenfunctions of (20), the inner product used being the same as the one defining the norm (21).

The approximation of (23) is a result of the finite number K used in the expansion. Following Ref 31, K is chosen such that convergence is reached; in practice, $K \approx 60$ was found to be sufficient. The 2-norm on the RHS of (23) can now be evaluated using SVD. This procedure gives both G_{MAX} and the K expansion coefficients of the disturbance associated with G_{MAX} ^{18,20}. Note that, since eigenfunctions have been expressed as an expansion in Chebyshev polynomials, all calculations are ultimately performed in terms of the Chebyshev expansion coefficients. In particular, the energy norm (21) and the weight matrix $\mathcal{M}$ are easily recast in terms of the expansion coefficients using the properties of Chebyshev polynomials and their derivatives (for details see Ref. 31).

IV. RESULTS

A. Modal Stability Properties

It can be shown that within inviscid theory,^{7,8} the stability of a rotating shear flow is analogous to that of Boussinesq convection in which the total base vorticity ($2\Omega - dU/dy$) plays the role of temperature gradient. The dimensionless instability criterion then states that total vorticity must be negative somewhere in the flow⁷ i.e.

$$\text{Ro} \frac{dU}{dy} > 1 . \quad (24)$$

The relative vorticity of the base flow $-dU/dy$ which is directed along the z direction, is always negative for both RB and RAS flows. Positive Rossby $\text{Ro} > 0$, thus corresponds to oppositely directed rotation and flow vorticity, that is why it is referred to, in the geophysical literature, as anti-cyclonic. This is the region we will consider here since negative Rossby $\text{Ro} < 0$ correspond to cyclonic case where this instability disappears.

Neutral stability curves of RB flow at $\text{Re} = 600$ and several Rossby numbers are shown in Fig. 2a. The region identified as “TS” corresponds to the (rotationally modified) Tollmien-Schlichting modes of the non-rotating Blasius flow. The TS region is only slightly modified by rotation, becoming discernibly larger only when Ro is below 300. The lower curves in Fig. 2a, identified by their Ro values, delineate the region of rotational instability. The largest growth rates are found for streamwise uniform modes ($\alpha = 0$) having a non-zero spanwise wavenumber β (Fig. 2b), that depends on the value of Ro , in agreement with previous results for other rotating shear flows.^{7,8,9,10} The extent of the rotationally unstable region grows rapidly with rotation, and is quite large at $\text{Ro} = 300$ which is the strongest rotation depicted in figure Fig. 2a. Ultimately, this instability is suppressed for very strong rotation

as examined below. Note that the rotational instability takes on much larger growth rates than the TS instability, as illustrated by the curves of constant growth rate shown in Fig. 2b for the case $Re = 600$, $Ro = 300$. More precisely the largest TS growth rate is found in this case to be $\sup_{\alpha,\beta}(\omega_i)_{TS} = 0.006$ while the maximum value in Fig.2b is $\sup_{\alpha,\beta} \omega_i = 0.145$

As in RB flow, an anti-cyclonic rotation for RAS leads, if not too strong, to a rotationally-induced instability which also reaches its maximum at $\alpha = 0$, while a cyclonic rotation ($Ro < 0$) is stabilizing. These rotationally unstable regions in (α, β) -plane are presented in Fig. 3a for $Re = 600$ and several Rossby numbers Ro . Note that growth rates of the rotational instability for RAS are of comparable magnitude to those found for RB flow (see Fig.3b for the case $Ro = 300$ where $\sup_{\alpha,\beta} \omega_i = 0.144$ is found). On the contrary, no TS neutral curves appear for RAS (Fig. 3a) for $Re = 600$. Recall that the AS profile is known to be much more stable with respect to TS instability compared with non-rotating Blasius flow. This effect is very apparent in the large critical Reynolds number of the AS profile ($Re_c = 54370$);¹ RAS flow thus lacks TS instability at $Re = 600$.

Re-stabilization –

In RB flow, the condition for instability (24) corresponds to $1/Ro < 0.5714$ ³² while in RAS flow the condition becomes $1/Ro < 1$. The re-stabilization of rotating boundary layer flows by strong anti-cyclonic rotation is confirmed by numerical computations. The curves in Fig. 4 represent the largest growth rates $\max \omega_i$ of this rotational instability found in the (α, β) -plane as a function of $1/Ro$ (this maximum was always found to occur for $\alpha = 0$). At the largest Reynolds number depicted in Fig. 4a, $Re = 6000$, re-stabilization of RB flow occurs at $1/Ro \approx 0.57$ while for RAS, re-stabilization occurs at $1/Ro \approx 0.98$ when $Re = 60000$, in agreement with the predicted values. Large positive rotations have also been found to re-stabilize channel flows,^{8,24} at Ro values consistent with the vorticity criterion

(24).

Since the rotational instability is fundamentally inviscid, the minimum Reynolds number below which the rotational instability is suppressed is quite low. The minimum Reynolds numbers below which no instability is found are $\text{Re}_C \approx 21$ at $\text{Ro}_C \approx 10.9$ for RB (see Fig. 4a) flow and $\text{Re}_C \approx 25.9$ at $\text{Ro}_C \approx 23.5$ for RAS flow (see Fig. 4b).

B. Transient Amplification

The effect of rotation on transient growth for the RB and RAS flows is quantified through the analysis of amplification gain $G_{MAX}(\alpha, \beta, \text{Ro}, \text{Re})$ as a function of streamwise wavenumber α , spanwise wavenumber β , Reynolds number and Rossby number. Note that, in calculating G_{MAX} and G_P values, a fixed time interval $[0, T]$ is used during which the maximum growth is allowed to occur; the value of T required to capture the maximum varies with Re and is adjusted accordingly in the calculations.

Non-rotating boundary layer flows are known to display the following transient growth features: (i) the most amplified disturbances tend to be three-dimensional with $\beta \neq 0$ and $\alpha = 0$; (ii) the peak amplification for large Reynolds number is proportional to the square of the Reynolds number i.e.

$$G_{MAX} \propto \frac{\beta^2 \text{Re}^2 T(k, \alpha \text{Re})}{k^2}, \quad (25)$$

where it is recalled that $k^2 = \alpha^2 + \beta^2$ and T is a function of k and αRe only; (iii) the time to achieve peak amplification increases linearly with the Reynolds number i.e. $t_{MAX} \propto \text{Re}$. For rotating boundary layers, scaling (25) or its straightforward consequence $G_P \propto \text{Re}^2$ is not preserved as shown below.

For non-rotating boundary layers $(U(y), 0, 0)$, the Reynolds scalings rely on the following

statements (see also Ref.23): upon performing the rescalings $\hat{t} = t/\text{Re}$, $\hat{\zeta} = \zeta/(\beta\text{Re})$, $\hat{v} = v$, equations (11)-(12) become dependent only on k^2 and αRe and the energy turns into

$$\|\mathbf{q}(\hat{\mathbf{t}})\|_E^2 = \int_0^L (|D\hat{v}|^2 + k^2|\hat{v}|^2)dy + (\beta\text{Re})^2 \int_0^L (|\hat{\zeta}|^2)dy. \quad (26)$$

When the Rossby number is present, the energy expression is still valid but, in addition to $k^2 = \alpha^2 + \beta^2$ and αRe , the parameters Ro and $\frac{(\beta\text{Re})^2}{\text{Ro}}$ explicitly appear in equations (11)-(12)

$$\left(\frac{\partial}{\partial \hat{t}} + i\alpha\text{Re}U\right)(D^2 - k^2)\hat{v} - i\alpha\text{Re}(D^2U)\hat{v} + \frac{1}{\text{Ro}}i(\beta\text{Re})^2\hat{\zeta} - (D^2 - k^2)^2\hat{v} = 0, \quad (27)$$

$$\left(\frac{\partial}{\partial \hat{t}} + i\alpha\text{Re}U\right)\hat{\zeta} - \frac{1}{\text{Ro}}i\hat{v} + i(DU)\hat{v} - (D^2 - k^2)\hat{\zeta} = 0. \quad (28)$$

The standard arguments are thus no longer valid when the Rossby number is present, implying that the classical scalings will not be replicated. The numerical computations which confirm this idea, are presented below with the observed scalings.

Rotating Blasius boundary layer –

In Fig.5, level curves of G_{MAX} in the (α, β) -plane are presented for RB flow in three cases: weak cyclonic rotation $\text{Ro} < 0$ (Fig.5a), no rotation (Fig.5b), and weak anticyclonic rotation $\text{Ro} > 0$ (Fig.5c), the Reynolds number being always fixed at $\text{Re} = 600$ which is just above the critical value $\text{Re}_c \approx 520$ for unstable Tollmien-Schlichting waves. The TS instability region is apparent along the α -axis centered at $\alpha \approx 0.3$ and has only minor influence on the transient growth (see below).

In the absence of rotation, the peak G_{MAX} value was found to occur at $\alpha = 0$ and $\beta = 0.651$ (Fig.5b), and to take the value $G_P = 545.8$ ($G_P = 545.9$ with $N = 75$ polynomials and $G_P = 545.8$ with $N = 125$). This value is in good agreement with other studies.^{18,33,34} From previous computations by Butler and Farrell¹⁸ ($G_P = 1514$ at $\text{Re} = 1000$) or Corbett and Bottaro³⁴ ($G_P = 1515$ at $\text{Re} = 1000$) the scaling law $G_P = 1.515 \times 10^{-3}\text{Re}^2$ should

be the correct one for non-rotating Blasius flow. Using this latter formula, it is found that $G_P = 545.4$ at $\text{Re} = 600$.

When the rotation is anti-cyclonic (Fig.5c) i.e. for $\text{Ro} > 0$, rotational instability of §IV(A) appears along the β -axis and the level curves of G_{MAX} are distorted in the neighborhood of the highlighted region of unstable normal modes. Moreover, the G_{MAX} values adjacent to the neutral curve are enhanced by the nearby modal instability, and the peak amplification occurs along the rotational neutral curve at $\beta \approx 1$. In such a case, transient growth must compete with the strong modal instability.

With cyclonic rotation (Fig.5a) i.e. for $\text{Ro} < 0$, G_{MAX} values are reduced in magnitude everywhere in the (α, β) -plane and the rotational instability is absent. In addition, G_P is now found at non-zero streamwise wavenumber (for $\text{Ro} = -1800$ and $\text{Re} = 600$, $\alpha \approx 0.12$), while the spanwise wavenumber slightly shifts from the value of the non-rotating case (for $\text{Ro} = -1800$ and $\text{Re} = 600$, $\beta \approx 0.75$). An optimal disturbance (hereafter denoted by OD) with weak streamwise dependence ($\alpha \neq 0$) is often referred to as oblique, and is more typical of plane Couette flow than of boundary layer flow. Here, the obliquity is a consequence of the Coriolis effects. The Ro dependence of the peak growth G_P is illustrated in Fig.6. Each point in this figure was obtained by first performing a calculation of G_{MAX} throughout the (α, β) -plane (like the one of Fig.5a), then finding the peak value, G_P , and the wavenumbers, α_P and β_P at which the peak occurs. Two Reynolds numbers are shown: $\text{Re} = 600$, marked by open circles, and $\text{Re} = 1800$, marked by dots.

The inset of Fig.6 shows the location in the $\alpha - \beta$ wavenumber plane corresponding to the plotted G_P values. When rotation is very weak, G_P is found at $\alpha_P = 0$, $\beta_P = 0.651$; as rotation increases, the location of G_P loops through the plane, eventually settling at $\beta_P = 0$ for strong rotation, with a streamwise wavenumber $\alpha_P(\text{Re})$ dependent on the Reynolds

number. The value $G_P = 16.70$ is found at $\alpha_P = 0.467$ for $\text{Re} = 600$ while $G_P = 51.02$ is found at $\alpha_P = 0.364$ when $\text{Re} = 1800$. These values are also recovered for strong values of anti-cyclonic rotation. The wavenumber α_P and G_P values at strong rotation agree with two-dimensional non-rotating transient growth calculations. Butler & Farrell¹⁸ give $G_P = 28$ at $\alpha_P = 0.42$ for the best optimal 2D ($\beta_P = 0$) disturbance for non-rotating Blasius flow at $\text{Re} = 1000$. At the same Reynolds number, we find $G_P = 28.4$ for $\text{Ro} = -0.5$ at $\alpha_P = 0.42$. These findings are consistent with the idea that strong rotation imposes a two-dimensional Taylor-Proudman régime.^{8,35}

The ratio of the two G_P curves in Fig.6 is a measure of the Re dependence of G_P over a range of Ro . From the figure, this dependence is clearly inconsistent with a Re^2 scaling throughout the entire Ro range. This Re dependence is explicitly shown in Fig.7a and 7c. For weak rotation ($\text{Ro} = -10^6$), G_P/Re^2 possesses a weak Re dependence (Fig.7a) which strengthens for slightly stronger rotations ($\text{Ro} = -10^5$). In the strong rotation régime (Fig.7c), no simple Re dependence is found for G_P in RB flow: although G_P seems linear in Re , a careful analysis reveals that this is not strictly correct. In addition, figure Fig.7c confirms that, for transient growth properties, the flow becomes increasingly two-dimensional in character as rotation increases. Note that, in a similar manner, the time t_p is not linear in Re for weak rotation ($\text{Ro} = -10^6$) (Fig.7b) while we obtain scaling $t_P = 0.78\text{Re}$ with no rotation. In the strong rotation régime (Fig.7d), t_P possesses no obvious scaling though one would guess by eye a $\sqrt{\text{Re}}$ law, which is not confirmed by a rigorous fit.

Rotating asymptotic suction flow –

The qualitative features found for RB flow are also recovered for RAS flow; the following presentation can therefore be relatively terse. Figure 8 is the equivalent of Fig. 5, but for RAS flow at $\text{Re} = 600$. AS flow is well below its critical value $R_c = 54370$ for TS

instability, so no TS region is present. The most amplified disturbances in the absence of rotation (Fig.8b) are again streamwise uniform ($\alpha = 0$) while for weak cyclonic rotation (Fig.8a) they begin to show weak streamwise variability ($\alpha \approx 0.07$ for the case of Fig.8a). Figure 9 is the RAS flow equivalent of Fig. 6; here, again, both $Re = 600$, marked by open circles, and $Re = 1800$, marked by dots, are calculated. These are the only known calculations of transient growth in RAS flow. For AS flow (i.e. no-rotating case), the values of G_P and β_P have appeared in recent works: Ref. 36 provides a scaling law of the form $G_P = 0.99Re^2$ which gives e.g. $G_P = 356.4$ at $Re = 600$. In the limit of very weak rotation, we find $G_P(Re = 600) = 358.12$ (or, when the transverse velocity V is included, $G_P(Re = 600) = 356.74$, in good agreement with Ref.36). As in RB, scalings $G_P \propto Re^2$ and $t_P \propto Re$ are not recovered, except for very weak rotation (Fig.10a and 10b). Again as in RB, a careful analysis does not reveal a clear scaling for G_P and t_P in the strong rotation régime (Fig.10c and 10d) though one would guess by eye a scaling in Re and $\sqrt{Re}$ respectively.

The inset of Fig.9 shows the location in the $\alpha - \beta$ wavenumber plane corresponding to the plotted G_P values. As in RB, the optimal disturbance in RAS flow makes an excursion in wavenumbers, starting at $\alpha_P = 0$, $\beta_P = 0.499$ ($\beta_P = 0.530$ when V is included) for very weak rotation, looping through the plane and settling on $\beta = 0$ and a Re -dependent $\alpha_P(Re)$ when rotation is strong. For instance, the value $G_P = 5.736$ is found at $\alpha_P = 0.670$ for $Re = 600$ while $G_P = 13.12$ is found at $\alpha_P = 0.617$ for $Re = 1800$. When V is included, these values shift to $G_P = 5.661$ at $\alpha_P = 0.675$ for $Re = 600$ and $G_P = 13.01$ at $\alpha_P = 0.621$ for $Re = 1800$. These same values are also recovered for strong values of anti-cyclonic rotation.

C. Optimal Disturbances

The most amplified disturbances in cyclonic RB and RAS flows possess a non-null streamwise wavenumber: they thus correspond to oblique vortices. The flow field of these disturbances can be calculated from its expansion coefficients, already obtained in the SVD solution of G_{MAX} . An example of the optimal disturbance (OD) in a weakly rotating RB flow, at $Re = 600$, $Ro = -1 \times 10^6$, is depicted in Fig.11 and can be compared to the OD for the classical Blasius flow at the same Reynolds. In figures Fig.11 and 12, the velocity field $v\hat{y} + w\hat{z}$ and the streamwise velocity component u are shown at a given streamwise location ($x = 0$). Due to the similarity of the optimal disturbances for RB and RAS flows, RAS examples are not shown.

While the OD in RB at very weak rotation $Ro = -1 \times 10^8$ is indistinguishable from the OD in non-rotating Blasius flow at both $t = 0$ and $t = t_P$, this is not so for larger but still weak rotations. Indeed the OD in RB at $Ro = -1 \times 10^6$ (Fig.11 a) –which resembles with apparent counter-rotating streamwise rolls, the OD in non-rotating Blasius flow at $t = 0$ (Fig.11c)– is such that the extrema of streamwise velocity u (Fig.11b) are not precisely aligned with the up- and down-flows (Fig.11a) between the vortices, as found in non-rotating Blasius flow (Figs.11c,d). This offset is still found in the OD at its greatest amplification at $t = t_P$. Except for a shift of phase, little change is seen in the u field. This explains why the G_P value is not too different from the one found in the non-rotating limit. The kinetic energy of the OD is initially mainly in the v or w components and not in u component. At $t = t_P$ it is contained mainly in u field.

The above features are enhanced at stronger rotations as depicted in Fig.12, where $Ro = -1800$: even the OD at $t = 0$ being profoundly modified. Finally, at very strong rotation

(e.g. $Ro = -1$ in Fig.13), two-dimensionality is imposed in the $x - y$ plane and the OD at $t = 0$ (Fig.13) clearly exhibits the characteristic tilting against the shear of the 2D Orr mechanism. At $t = t_P$, the shear has evolved the initial disturbance into vortices counter-rotating along the z -axis (Fig.13).

V. CONCLUSIONS

This work has expanded on previous studies of boundary layer flows to account for frame rotation. In particular, the temporal evolution of three-dimensional disturbances has been studied for RB and RAS boundary layer flows in the presence of spanwise rotation. Normal mode and transient growth disturbances properties were calculated and compared for the two flows. Rotational modal instability, similar to that known for rotating channel and free shear flows, was found for weak anti-cyclonic rotation in RB and RAS; neutral curves, growth rates and the critical point were calculated for both flows. Rotating boundary layer flows were also found to exhibit transient growth. In the modally stable cyclonic regime the transient growth properties strongly depend on the rotation rate. In particular: (i) peak growth factors are reduced by rotation; (ii) even at weak rotation, the classical Re^2 dependence is not recovered; (iii) optimal disturbances take the form of oblique vortices which transform continuously from streamwise uniformity ($\alpha = 0$) when rotation is very weak to spanwise uniformity ($\beta = 0$) when rotation is strong, this last feature being a consequence of a Taylor-Proudman régime.

It is anticipated that the results presented here may be useful in dealing with geophysical and astrophysical flows, where rotation is important and curvature is often negligible. Most noteworthy is the example of Keplerian flow in an accretion disk, where no purely hydrodynamic inviscid linear eigenvalue instability has been identified. A study of transient

growth in two-dimensional accretion disks³⁷ has recently been performed and further inquiry is already under way. The problems analyzed in this work constitute an interesting element of disk flow studies.

Finally let us mention that the longitudinal roll instability in rotating shear flow exhibits weak downstream development⁹. Because the development is weak and because a great deal of closely related previous work^{7,8,10,11,38} is based on temporal theory, this study adopted a temporal framework. However recent spatial analyses of ordinary boundary layer transient growth^{39,40,41} are shown to be more realistic with respect to observations.⁴² In future investigation, this aspect should be envisaged to complement the present temporal theory.

APPENDIX: The transverse velocity in the presence of rotation.

Transverse velocity V is normally neglected in the classical temporal stability analysis of Blasius flow, being of the same order as other neglected terms. The effect of this assumption on the instability normal modes is well documented for non-rotating AS and Blasius flows (see standard references, e.g. Ref. 1). In this appendix, we examine the effect of this assumption on two aspects which have not been previously studied: (a) the effect of V on transient growth properties with or without rotation; (b) the effect of V on the rotational normal mode instability properties. We consider these two effects on the AS and RAS flows since they are true Navier-Stokes solution when V is present which authorizes a quantitative

comparison between the simplified analysis ($V = 0$) and the complete one.

An overview of the effect of V on the transient growth properties of the AS flow (i.e. non-rotating) can be found in Table I. Briefly, the neglect of V has little effect on the peak growth factors G_P of AS flow, less than one percent. The wavenumber of peak growth, β_P , is shifted to larger values when V is included in AS calculations, but the shift is relatively small. The two cases are illustrated in Fig. 14 where level surfaces of $G_P(\alpha, \beta)$ are shown for the AS calculated with and without the V term. As regard t_P values, we obtain $t_P = 1.145\text{Re}$ when V is included which agrees with Ref.36 and we find $t_P = 1.331\text{Re}$ when V is neglected.

The effect of V on the rotational instability neutral curves and growth rates is small, except near the critical point $(\text{Re}_C, \text{Ro}_C)$. These properties are illustrated for RAS in Fig.15a, showing the shifted neutral curves, and Fig.15b, showing the modified growth rates. When V is included, the location of the critical point shifts from $\text{Re}_C = 25.9, \text{Ro}_C = 23.5$ to $\text{Re}_C = 33.7, \text{Ro}_C = 14.6$, as seen in Fig.16 (compare to Fig.4(b)).

Under rotation, the effect of V on the transient growth properties of the RAS remains negligible. To show this we display in Fig.17 the differences in peak growth factors G_P calculated with and without the V term for $\text{Re} = 600, \text{Ro} = 1800$.

FIG. 1: Sketch of the flow configuration.

FIG. 2: (a) Neutral curves of RB flow at Reynolds number $Re = 600$ and various Rossby numbers Ro ; α and β are the streamwise and spanwise wavenumber, respectively. (b) Curves of constant growth rate ω_i for RB flow at $Re = 600$ and $Ro = 300$.

FIG. 3: (a) Neutral curves of RAS flow at Reynolds number $Re = 600$ and various Ro ; (b) Curves of constant growth rate ω_i for RAS flow at $Re = 600$ and $Ro = 300$.

FIG. 4: (a) Largest growth rates $\max \omega_i$ for anti-cyclonic RB flow at Reynolds numbers $Re = 25, 60, 600, 6000$ (curves bottom to top); Inset: projection of the neutral surface $\omega_i(\beta, Re, Ro) = 0$ onto the $Re - Ro$ plane, showing the critical point $Re_C = 21.005, Ro_C = 10.9$; (b) Same as (a) but for RAS at $Re = 40, 60, 600, 6000, 60000$ (curves bottom to top); Inset: critical point $Re_C = 25.9, Ro_C = 23.5$.

FIG. 5: Level curves of G_{MAX} in the (α, β) -plane for RB flow at $Re = 600$ and for weak cyclonic ($Ro = -1800$) rotation (a), no rotation (b), and weak anti-cyclonic ($Ro = 1800$) rotation (c). Regions of modal instability are shaded.

FIG. 6: Peak amplification factors G_P of RB flow at $Re = 600$ and $Re = 1800$ as a function of cyclonic $Ro < 0$; Inset: corresponding location in the wavenumber $\alpha - \beta$ plane of the optimal disturbance associated with G_P values in the figure; weak rotation cases lie along the β axis while strong rotation cases lie along α .

FIG. 7: (a) G_P/Re^2 of RB flow as a function of Re for two weak rotation cases $Ro = -10^5$, $Ro = -10^6$ and no-rotation; (b) t_P/Re of RB flow as a function of Re for the same cases as (a); (c) G_P of RB flow as a function of Re for strong rotation, $Ro = -1$, and two-dimensional disturbances; (d) t_P of RB flow as a function of Re for the same cases as (c).

FIG. 8: Level curves of G_{MAX} in the (α, β) -plane for RAS flow at $Re = 600$ for weak cyclonic ($Ro = -1800$) rotation (a), no rotation (b), and weak anti-cyclonic ($Ro = 1800$) rotation (c). Regions of modal instability are shaded.

FIG. 9: Peak amplification factors G_P of RAS flow at $Re = 600$ and $Re = 1800$ as a function of cyclonic $Ro < 0$; Inset: corresponding location in the $\alpha - \beta$ plane of the optimal disturbance associated with G_P values in the figure; weak rotation cases lie along the β axis while strong rotation cases lie along the α axis.

FIG. 10: (a) G_P/Re^2 of RAS flow as a function of Re for two weak rotation cases $Ro = -10^5$, $Ro = -10^6$ and no-rotation; (b) t_P/Re of RAS flow as a function of Re for the same cases as (a); (c) G_P of RAS flow as a function of Re for strong rotation, $Ro = -1$, and two-dimensional disturbances; (d) t_P of RAS flow as a function of Re for the same cases as (c).

FIG. 11: (a) Velocity vectors $v\hat{y} + w\hat{z}$ of the most amplified disturbance in cyclonic RB flow at $Re = 600$ and $Ro = -10^6$. The disturbance is shown at $t = 0$ (left) and at the time of maximum growth (right). (b) Streamwise velocity u for OD of (a). (c) Velocity vectors $v\hat{y} + w\hat{z}$ for non-rotating Blasius flow at $Re = 600$. The disturbance is shown at $t = 0$ (left) and at the time of maximum growth (right). (d) Streamwise velocity u for OD of (c).

FIG. 12: (a) Velocity vectors $v\hat{y} + w\hat{z}$ of the most amplified disturbance in cyclonic RB flow at $Re = 600$ and $Ro = -1800$. The disturbance is shown at $t = 0$ (left) and at the time of maximum growth (right). (b) Streamwise velocity u for OD of (a).

FIG. 13: Velocity vectors $u\hat{x} + v\hat{y}$ in the $x - y$ plane of the most amplified disturbance in cyclonic RB flow at $Re = 600$ and $Ro = -1$. The disturbance is shown at $t = 0$ (left) and at the time of maximum growth (right).

FIG. 14: Comparison of the level curves of G_{MAX} in the (α, β) -plane for AS flow calculated with V included (solid curves) and V neglected (dashed). The peak growth is found at $\alpha_P = 0$ and $\beta_P = 0.529$ (V included) or $\beta_P = 0.499$ (V neglected).

FIG. 15: (a) Neutral curves of RAS flow at Reynolds number $Re = 600$ and three Ro ; (b) Curves of constant growth rate ω_i for RAS flow at $Re = 600$ and $Ro = 300$. In the figure, the dashed curves correspond to calculations in which V was neglected, reproducing Fig.3; the solid curves were computed with V included.

FIG. 16: Largest growth rates $\max \omega_i$ for anti-cyclonic RAS flow with V included at Reynolds numbers $Re = 40, 60, 600, 6000, 60000$ (curves, bottom to top); Inset: projection of the neutral surface $\omega_i(\beta, Re, Ro) = 0$ onto the $Re - Ro$ plane, showing the critical point at $Re = 33.77, Ro = 14.5$. To be compared to Fig.4(b).

FIG. 17: Comparison of maximum transient growth level curves for RAS flow at $Re = 600, Ro = 1800$, calculated with V included (solid curves) and V neglected (dashed curves). The peak growth factor is $G_P = 130.79$ (V included) or $G_P = 129.86$ (V neglected).
